## Address

'Ravichandram' Survey No-101/1, Plot, No-23, Mundada Nagar, Jalgaon (M.S.) 425102

Sonpeth, Dist. Parbhani (MS) India  
Jointly organized

One Day International Multi disciplinary Conference (Blended Mode)

“Recent Advancements in Commerce & Management, Innovation & Entrepreneurship,  
Science & Technology, Pharmacy & Health, Humanities &  
Social Sciences, Education & Environment”

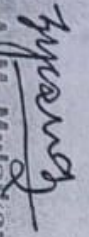

Date: 20 April, 2022

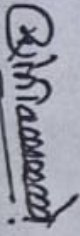

Certificate of Participation

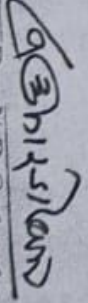

This is to certify that, Prof./Dr./Mr./Mrs./Miss C. J. Kadam Has

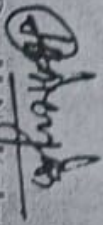

of Maharashtra Mahavidyalaya, Nilanga actively participated in One Day International Multidisciplinary Blended conference on, “Recent Advancements in Commerce & Management, innovation & Entrepreneurship, Science & Technology, Pharmacy & Health, Humanities & Social Sciences, Education & Environment” in Online/Offline mode and presented his/her research paper entitled as “Variation of Sunlight Intensity With Time” Hence certified.

  
Dr. N.V. Pinamkar

**Abstract:** Investigation on the sunlight intensity impact & ambient temperature on the inorganic solar panels in summer season , 18<sup>th</sup>Feb-2020 at Latur city , Maharashtra state , India was carried out. It was noticed that the max power ( $P_{max}$ ) point is shifting up (increased) by the proceeding of time from 08:00 am to 5:00 pm. Beyond 12 pm the intensity of sunlight showed a non-monotonic behavior, because of change of sun position and the direction at which the surface of the panel is illuminated. The effect of sunlight intensity on the electrical parameters of the solar panels is elaborated.  $V_{oc}$  (Open circuit voltage) remained unchanged where  $I_{sc}$ (Short circuit current) shows increment of its value because of the fact that charge carriers acquire enough kinetic energy to move towards their electrodes before they recombine together. Efficiency decreases with the increase of temperature so that, Fill Factor showed a reverse trend.  $I_{sc}$  increment with the increase of temperature.

**Keywords:**Sunlight intensity, ambient temperature , fill factor, inorganic solar panels, Short-circuit current, Open-circuit voltage , Monotonic.

### Introduction:

Solar power is amazing. On average, every square meter of Earth's surface receives 163 watts of solar energy. A gigantic power station in the sky up above us, sending out clean, non-stop energy for free. The Sun, a seething ball of nuclear power, has enough fuel onboard to drive our Solar System for another five billion years—and solar panels can turn this energy into an endless, convenient supply of electricity. The energy the Sun sends out arrives on Earth as a mixture of light and heat. Both of these are incredibly important—the light makes plants grow, providing us with food, while the heat keeps us warm enough to survive—but we can't use either the Sun's light or heat directly to run a television or a car. We have to find some way of converting solar energy into other forms of energy we can use more easily, such as electricity. And that's exactly what solar cells do. A solar cell is an electronic device that catches sunlight and turns it directly into electricity. It's about the size of an adult's palm, octagonal in shape, and colored bluish black. Solar cells are often bundled together to make larger units called solar modules, themselves coupled into even bigger units known as solar panels. The cells in a solar panel are designed to generate electricity. A solar panel's cells generate power by capturing sunlight. They are sometimes called photovoltaic (PV) cells because they use sunlight ("photo" comes from the Greek word for light) to make electricity (the word "voltaic" is in reference to Italian electricity pioneer Alessandro Volta, 1745–1827). Most cells convert about 10–20 percent of the energy they receive into electricity. A typical, single-junction silicon solar cell has a theoretical maximum efficiency of about 30 percent, known as the **Shockley-Queisser limit**. That's essentially because sunlight contains a broad mixture of photons of different wavelengths and energies and any single-junction solar cell will be optimized to catch photons only within a certain frequency band, wasting the rest. Some of the photons striking a solar cell don't have enough energy to knock out electrons, so they're effectively wasted, while some have too much energy, and the excess is also wasted. The very best, cutting-edge laboratory cells can manage just under 50 percent efficiency in absolutely perfect conditions using multiple junctions to catch photons of different energies. When we place a layer of n-type silicon on a layer of p-type silicon, a barrier is created at the **junction** of the two materials. If we shine light onto the sandwich, photons enter our sandwich, they give up their energy to the atoms in the silicon. The incoming energy knocks electrons out of the lower, p-type layer so they jump across the barrier to the n-type layer above and flow around the circuit. The more light that shines, the more electrons jump up and the more current flows. This is what we mean by photovoltaic—light making voltage. The inorganic semiconductor materials used to make photovoltaic cells include crystalline, multicrystalline, amorphous, and microcrystalline Si, the III-V compounds and alloys, CdTe, and the chalcopyrite compound, copper indium gallium diselenide (CIGS). Inorganic photovoltaic cells utilize crystalline elements as a light absorber, organic photovoltaic cells utilize molecules or polymers to convert sunlight into electricity.

**There are 3 types of solar panels primarily used in the solar industry:**

1. Monocrystalline solar panels.
2. Polycrystalline solar panels.
3. Thin film (amorphous) solar panels.

A typical organic solar cell consists of two semiconducting layers made of plastic polymers and other flexible materials. The cell generates electricity by absorbing particles of light, or photons. This continuous movement of electrons from hole to hole produces an electric current. Solar panels available in the market are made from inorganic semiconductor materials, of them approximately 85% are based on crystalline silicon [1]. Silicon can offer many advantages like high crystal quality, stability, non-pollutant, and ideal band gap ( $E_g=1.11$  eV) for solar energy absorption [1]. If the light intensity and temperature of the environment changes, the solar cells performance will be affected. i.e., the response of the absorbent layer in solar cells is changed in terms of charge carrier generation and recombination[2], when it is subjected to the variation of light intensity and temperature. Light intensity is changed daily due to the rotation of the earth around its own axis, and seasonally due to the rotation of the earth around the sun [3]. Solar panels are made from regularly arranged arrays of solar cells interconnected together according to the required voltage and current. Little attention has been paid on the practical investigation of inorganic solar panels under different sunlight intensities and temperatures in outdoor situations. Therefore, in this research work we investigate the effect of light intensity and ambient temperature on the electrical performance of inorganic solar panels based on silicon. The solar panels are installed in an outdoor condition in Latur city, located in Maharashtra state, India.

**Methodology:**

Two small silicon based solar panels (Leybold Didactic GMBH) with dimension of 25×25 cm<sup>2</sup> connected in series were installed on the roof of a home building specified for the investigations. The panels are inclined 36 degrees due south and a light meter was used to measure the light intensity, accordingly. Two digital multimeters were utilized to measure the current and voltage produced by the panels, while a variable resistor (1 Ω to 100 kΩ) was connected as a load and a thermometer was used to measure the ambient temperature. The maximum power (P<sub>max</sub>) delivered from the solar panels and the fill factor (FF) were calculated by the following equations:

$$P_{max} = V_{mp} \times I_{mp} \quad (1)$$

$$FF = P_{max} / (V_{oc} \times I_{sc}) \quad (2)$$

Where, I<sub>sc</sub> and V<sub>oc</sub> are short-circuit current and open-circuit voltage of the solar panels, respectively.

**Table No.1**

| Sr. No. | Time(hrs) | Intensity(kLux) |
|---------|-----------|-----------------|
| 1       | 08:00 am  | 53.62           |
| 2       | 09:00 am  | 67.5            |
| 3       | 10:00 am  | 98.47           |
| 4       | 11:00 am  | 110.15          |
| 5       | 12:00 pm  | 117.75          |
| 6       | 01:00 pm  | 99.51           |
| 7       | 02:00 pm  | 92.24           |
| 8       | 03:00 pm  | 84.12           |
| 9       | 04:00 pm  | 65.27           |
| 10      | 05:00 pm  | 23.74           |

**Figure 1: The intensity of sunlight versus time from 8:00 am to 5:00 am.**

## s And Discussion:

Graph is plotted between intensity of sunlight and time from 8:00 am to 5:00 pm recorded on 18<sup>th</sup> Feb 2020. Bar graphs shows that as the time increases from morning 8:00 am to noon 12:00 pm, sunlight intensity is continuously increasing and the highest peak is obtained at 12:00 pm i.e. the maximum sunlight intensity is obtained as 117.75 kLux. Further after past meridian it is seen that the intensity goes on decreasing making the intensity spectra to show a non-monotonic change behavior. This is because of the variation of the sun, position of the sun and the direction at which the surface of the solar panel will be illuminated. [4]. From this we can predict that the quality of electrical power generated by the solar panel will be good, iff, the solar intensity is high/good. Voltage versus current characteristics are drawn in the fig.2 of the solar panel in the Fig.2, of the solar panel under investigation at three different times on 18<sup>th</sup> Feb-2020. It is found that the current generated by the solar panels at 12:00 pm was increased by the preceding time 11:00 am (before noon). As the sunlight intensity increases the photo electron generations are also increased [3], and hence current generation will be large at the output load. After past meridian with the decrease in sunlight intensity, the current generation also decreases. The shape of the V-I curves at three different irradiation times defines the inherent property of bilayer solar cells where a knee position on each curve is definitely presented [6]. From this V-I characteristics it is seen that the production of maximum power point ( $P_{max}$ ) at the external load is exactly matched with the internal resistance of the solar panel [7]. The power generated by the solar panels used in this experiment for three different times is recorded. It is observed that the maximum power point ( $P_{max}$ ) at mid noon 12:00 pm is increased by the preceding time 11:00 am and past meridian time 1:00 pm. The highest reachable power for the solar panels is considered to be mid noon (12:00 pm), and it was counted to be 1.124 W. It is noted that the increment in the maximum power is not regular and there are some deviations compared to the regular change of time because of secondary effect of ambient temperature acting upon the performance of the solar panels. The electrical parameters  $V_{oc}$  (open circuit voltage),  $I_{sc}$  (Short circuit current) and FF (Fill Factor) are studied. Study shows that the  $V_{oc}$  remains relatively unchanged, because it is directly correlated to the energy gap of the P-N junction active material which is very less affected by variation of sunlight intensity. Whereas  $I_{sc}$  increases towards its value, because the charge carriers (Free electrons and holes) acquire enough kinetic energy to move towards their corresponding electrodes effectively before they recombine together. Surrounding temperature is also one of the factors which shows effect on the generation of electric power of the solar panels. Temperature changes are observed in the morning and evening because of the wind, cloud and sun position. Fill Factor is the ratio of maximum obtainable power to the product of  $V_{oc}$  &  $I_{sc}$ . Higher the value of fill factor, better is the quality of solar panel. It was found that there are no any changes seen in the fill factor (FF) for the variation of temperature  $10^{\circ}C$  to  $36^{\circ}C$ . FF also shows increment in its value, for the increase in the ambient temperature.

The study of variation of sunlight intensity and ambient temperature effect with the inorganic solar panels in Latur city, Maharashtra state, India, was carried out on 18<sup>th</sup> Feb-2020. Maximum sunlight intensity was attained at mid noon (12:00 pm) and then it is decreased showing non monotonic behavior after past meridian. The maximum sunlight intensity was recorded as 117kLux at 12:00 pm. This can be ascribed with the variation of sun position, orientation and its direction at which the surface of the panel is illuminated. As the sunlight intensity is increased, which in turn increases the photoelectrons, resulting in the increased load current. The maximum solar electric power generated by the inorganic solar panels was 1.124W at 12:00 pm. The electrical parameters of the inorganic solar panels  $V_{oc}$ ,  $I_{sc}$  & FF are studied. Study of these parameters shows that  $V_{oc}$  remains relatively unchanged whereas  $I_{sc}$  shows increment in its value which can be ascribed because the charge carriers (free electrons and holes) acquire enough K.E. to move towards their corresponding electrodes effectively before they recombine together. Fill factor FF, which indicates the quality of the solar panel, is observed that, its value increases with the increase in ambient temperature.

temperatures. Then normalized susceptibility was obtained from the ratio of  $(\chi/\chi_{RT})$  where  $\chi_{RT}$  is room temperature susceptibility. Typical plot of normalized susceptibility  $(\chi/\chi_{RT})$  versus temperature is presented in the Figure 2. From this plot it is seen that for magnesium ferrite, the susceptibility slowly increases and reaches peak value with temperature and suddenly drops to zero. The sudden drop of  $\chi/\chi_{RT}$  curve shows the formation of single phase cubic spinel [8]. The increases in susceptibility with peak values suggests there is existence of Multidomain (MD) particles in the material [9]. The peak is found to suppress with substitution of  $Gd^{3+}$  in  $MgFe_2O_4$  and also Curie temperature ( $T_c$ ) decreases with  $Gd^{3+}$  content. For the composition  $x = 0.2$ ;  $y = 0, 0.05$  and  $0.1$ , susceptibility is found to be independent on temperature upto  $T_c$  and after  $T_c$  it suddenly drops to zero. Such nature of curve indicates that the presence of SD particles in the materials [9]. Joshi et al [10] also reported similar behavior in Mg-Zn ferrite system. The compositions with  $x = 0.4$  and  $x = 0.6$  for  $y = 0, 0.05$  and  $0.1$  shows exponential decrease in susceptibility indicating SD to SP transition. The composition with  $x = 0.8$  and  $x = 1$  with  $y = 0, 0.05$  and  $0.1$  shows paramagnetic behavior at and above room temperature.

Curie temperatures ( $T_c$ ) obtained from susceptibility plots are presented table 1. The Curie temperature measurement of all the samples was also been carried out by the method suggested by Loria- Sinha [11] and also presented in the table 1. These values are found to be in good agreement with the values obtained from temperature dependence of normalized susceptibility. On substitution of  $Zn^{2+}$  in  $MgFe_2O_4$  Curie temperature found to decrease. This is because substituted  $Zn^{2+}$  ion invariably occupies tetrahedral (A) site, resulting into decrease in A-B interactions [12]. The composition with  $x= 0.8$  and  $1.00$  shows paramagnetic behavior at room temperature, their Curie temperature lies below room temperature. Substitution of  $Gd^{3+}$  ion, Curie temperature of each composition is found to decrease. This is attributed to dilution of B-B interaction [12]. On substitution  $Gd^{3+}$  ion occupies B-site replacing equivalent  $Fe^{3+}$  ions and so also decrease in magnetization at B-site.
